GERMAN-AUSTRIAN RECOMMENDATIONS FOR HIV1- THERAPY IN PREGNANCY AND IN HIV1-EXPOSED NEWBORN – UPDATE 2008

Common declaration*
of
The German AIDS-society (DAIG)
The Austrian AIDS-society (OEAG)
of the HIV-AIDS competence network
as well as
The Robert-Koch Institute Berlin (RKI)
The German Association of Physicians specialized in HIV Care (DAGNAE)
The German Society of Pediatric and Youth Medicine (DGKJ)
The German AIDS Pediatric Association (PAAD)
The German Society of Obstetrics and Gynecology (DGGG)
The National Reference Center for Retroviruses (NRZ)
German AIDS Assistance (DAH)

Updated by
Dr. med. Bernd Buchholz (University Medical Centre Mannheim, Pediatric Clinic), Dr. med. Matthias Beichert (Mannheim, Gynecology and Obstetrics Practice), Dr. med. Ulrich Marcus (Robert Koch Institute, Berlin), Dr. med. Thomas Grubert, Dr. med. Andrea Ginkelmaier (Gynecology Clinic of the Ludwig Maximilians University of Munich) Dr. med. Annette Haberl (HIV-Department, J. W. Goethe-University Hospital, Frankfurt) and Dr. med. Brigitte Schmied (Otto-Wagner Spital, Vienna)

* In July 2008 the following recommendations were sent for discussion per e-mail to the participants/specialists as per particulars given below and to all members of the German AIDS-society (DAIG). The final version was prepared on the occasion of a consensus building conference in Cologne on September 5th 2008.

The specialists included (in alphabetical order):

Beichert M (Mannheim) Graefe K (Hamburg) Kästner R (München) Schaferger A (Berlin)
Bogner J (München) Gröger S (Hamburg) Königs C. (Frankfurt) Schlechauf D (Berlin)
Brockmeyer N (Bochum) Grosch-Wörner I (Berlin) Korn K (Erlangen) Schmied B (Wien)
Buchholz B (Mannheim) Grubert T (Ravensburg) Kremer H (Miami) Sonnenberg-Schwan U
Cordes C (Berlin) Gürtler L. (Frankfurt) Marcus U (Berlin) (München)
Feiterna-Sperling C. (Berlin) Haberl A (Frankfurt) Nichues T (Krefeld) Stögerer M (Graz)
Funke A-M (Bremen) Hien S (Mannheim) Öttinger A (Linz) Vocks-Hauck M (Berlin)
Ginkelmaier A (München) Hollwitz B (Hannover) Reitter A (Frankfurt) von Weizäcker K (Berlin)
Abstract: German-Austrian recommendations for HIV1-therapy in pregnancy - Update 2008
Bernd Buchholz (University Medical Centre Mannheim, Pediatric Clinic), Matthias Beichert (Mannheim, Gynecology and Obstetrics Practice), Ulrich Marcus (Robert Koch Institute, Berlin), Thomas Grubert, Andrea Gengenmaier (Gynecology Clinic of the Ludwig Maximilians University of Munich), Dr. med. Annette Haberl (HIV-Department, J. W. Goethe-University Hospital, Frankfurt), Dr. med. Brigitte Schmied (Otto-Wagner Spital, Wien). In Germany during the last years about 200-250 HIV1-infected pregnant women delivered a baby each year, a number that is currently increasing. To determine the HIV-status early in pregnancy voluntary HIV-testing of all pregnant women is recommended in Germany and Austria as part of prenatal care. In those cases, where HIV1-infection was known during pregnancy, since 1995 the rate of vertical transmission of HIV1 was reduced to 1-2%. This low transmission rate has been achieved by the combination of anti-retroviral therapy of pregnant women, caesarean section scheduled before onset of labour, anti-retroviral post exposition prophylaxis in the newborn and refraining from breast-feeding by the HIV1-infected mother. To keep pace with new results in research, approval of new anti-retroviral drugs and changes in the general treatment recommendations for HIV1-infected adults, in 1998, 2001, 2003 and 2005 an interdisciplinary consensus meeting was held. Gynaecologists, infectious disease specialists, paediatricians, pharmacologists, virologists and members of the German AIDS Hilfe (NGO) were participating in this conference to update the prevention strategies. A fifth update became necessary in 2008. The updating process was started in January 2008 and was terminated in September 2008. The guidelines provide new recommendations on the indication and the starting point for HIV1-therapy in pregnancies without complications, drugs and drug combinations to be used preferably in these pregnancies and updated information on adverse effects of anti-retroviral drugs. Also the procedures for different scenarios and risk constellations in pregnancy have been specified again. With these current guidelines in Germany and Austria the low rate of vertical HIV1-transmission should be further maintained.

Key words: Pregnancy, HIV-therapy, HIV-status, HIV-testing, anti-retroviral drugs, recommendations

INTRODUCTION

The German-Austrian recommendations for HIV1-therapy in pregnancy reflect the current international knowledge and the experience of German clinical settings specialized in the treatment of HIV1-positive pregnant women. Even though all constellations, scenarios and contingencies of a pregnancy can not be considered within the scope of these recommendations, they are designed as scientifically-based guidelines. The most important and most frequent questions and problems which doctors, who treat HIV1-positive expectant mothers are facing, irrespective of whether they are experienced in the care for such pregnancies or not, are covered in these guidelines.

The medical measures recommended in these guidelines are helpful for every health care professional, who advises a HIV1-positive pregnant woman. Therefore these recommendations should be available in every delivery room. In case of obstetric emergencies the tables of these recommendations can be used as emergency plan.

It is also urgently recommended, that an HIV post-exposure prophylactic emergency set be kept in stock by the hospital and that all medical personnel involved is informed about indications and procedures related to HIV post-exposure prophylaxis after occupational HIV1-exposure (e.g. following needle prick or knife injuries to the operating surgeon).

Therapeutic recommendations can never replace extensive experience with patients and their specific problems. Therefore antenatal care of HIV1-positive expectant mothers, considering the many uncertainties associated with pregnancy, should be performed in- or in cooperation with specialized centers.

Without any medical measures to prevent mother to child transmission of HIV1 up to 40% of the HIV1-exposed newborn are HIV1-infected. In those cases, where HIV1-status of the pregnant women was known during pregnancy, since 1995 the rate of vertical transmission of HIV1 was reduced to 1-2% in Germany and Austria [140]. This low transmission rate has been achieved by the combination of anti-retroviral therapy of pregnant women, caesarean section scheduled before onset of labour, anti-retroviral post exposure prophylaxis in the newborn and refraining from breast-feeding by the HIV1-infected mother.

All measures necessary for the prevention of vertical HIV1-transmission can only be employed, if the HIV-infection status of the expectant mother is known. Risk factors for an HIV-infection, such as origin from a an HIV epidemic region, current or previous intravenous drug abuse or sexual intercourse with an HIV-infected partner, can not always be identified amongst all pregnant HIV1-infected individuals. For that reason an HIV antibody test should be offered to every pregnant women together with competent personal counseling in regard to possible consequences in the case of a positive test result (see also in 2007 updated German prenatal care guidelines und the therefore created leaflet “HIV-testing in pregnancy” as information of all pregnant women). If necessary this must be carried out with an interpreter and cultural mediation, even if the patient needs to be referred to a specialized center for this purpose. By German law the explicit approval of the pregnant mother is required for HIV-testing, which routinely consists of an ELISA screening test. A positive test result must be confirmed by Western Blot [1, 2]. If the patient is counseled by her gynecologist alone, addresses and telephone numbers of additional experts should be made available to the expectant mother. The personal and medical consequences of any positive test result for the woman should also be discussed in the counseling. Furthermore a competent pediatrician should con-
tribute to the counseling about transmission risks, follow-up tests and the course of HIV1-infection in a child.

As with many other problems in pregnancy, the welfare of the child must be weighed up against that of the mother when deciding for therapeutic/prophylactic measures against HIV1.

The goals of interdisciplinary co-operation between general practitioners, obstetricians and pediatricians in the treatment of HIV1-exposed expectant mothers and HIV1-exposed newborns are: 1) the prevention of mother to child transmission of HIV, and 2) the optimal treatment of pregnant women combined with minimal adverse effects in the expectant mother and in the unborn child.

Mothers with a high viral load and/or low t-helper cell numbers transmit HIV1 more frequently to their children [3, 4, 5], therefore successful therapy of the mother is also beneficial for the child. Risks for the child that might arise from intrauterine exposure to anti-retroviral combination therapies are still uncertain since data regarding pharmacokinetics, pharmacodynamics, embryotoxicity and fetotoxicity of these drugs are lacking [6, 7, 8, 9, 10, 11, 12, 13].

Basic and clinical research data suggest multiple risk factors which contribute to vertical HIV1-transmission [3, 4, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25]. Combined interventions as described in the following chapters can reduce the HIV1-transmission rate below 2% [16, 26, 27, 28].

The recommendations for diagnostic and therapeutic procedures given here are based on published study results wherever these were available. Such study results, however, are not available for all practical problems and questions, so that often clinical experience and expert opinions must be resorted to.

Even if the goal of these recommendations is the optimal treatment of mother and child based on the most recent findings, it should be stressed that the decision for the recommended diagnostic and therapeutic measures ultimately must be made in agreement with the expectant mother. This means that a refusal of a recommended diagnostic and/or therapeutic measure must also be respected, wherever the consent of an expectant mother can not be acquired despite adequate counseling.

After a detailed analysis of data and publications, a number of procedures were developed for specific situations. Most common situations and scenarios were considered. For all other situations however, individual decision on a case-by-case basis are necessary.

The following situations were discussed and consensus recommendations were made:

1. Prenatal care
2. Indication for anti-retroviral treatment and therapeutic regimens during pregnancy
2.1 Indication for anti-retroviral treatment
2.2 Resistance testing
2.3. Initial therapeutic regimen
2.4. Management of HIV1-positive pregnant women with Hepatitis-co-infection
2.4.1 Management of HIV1-positive pregnant women with Hepatitis B virus (HBV) co-infection
2.4.2 Management of HIV1-positive pregnant women with Hepatitis C virus (HCV) co-infection
2.5 Interruption of anti-retroviral therapy during the 1st trimester of the pregnancy
3. HIV1-transmission prophylaxis with standard risk profile
4. Risk-adapted transmission prophylaxis
4.1 Multiple pregnancy, premature labor and premature infants 33rd(+) - 36th(-)GW and maternal viral load 3000-10000 HIV-copies/ml before birth
4.2 Amnion infection syndrome/amnionitis, (premature) rupture of membranes >4h, premature birth <33rd(+) GW and viral load increase at the end of pregnancy >10 000 HIV copies/ml
4.3 Incision injury of the child/ aspiration and/or ingestion of blood contaminated amniotic fluid
5. Procedures with incomplete transmission prophylaxis
5.1 With verified HIV1-infection
5.2. Situations with unclear HIV1-infection status
6. Mode of delivery
7. Prenatal care in the delivery room
8. Postnatal prophylaxis of the newborn
9. Refraining from breast-feeding
10. Postnatal care of the HIV1-exposed child and preparation of a surveillance register
11. Phone-Hotline, notification of unexpected observations and experiences

* Clinical end point studies for new substances are no longer carried out due to the fact that conditions for licensing by the FDA and the EMEA have changed.
The recommendations were graded as outlined in the German-Austrian guidelines for the anti-retroviral Therapy of HIV1-infection [29]. Unless the results of voting are indicated, the recommendation was agreed upon unanimously.

1. Prenatal care

Upon diagnosis of HIV1 in a pregnant woman, an interdisciplinary center specialized in HIV care should be contacted immediately. From that point onwards the woman should be treated in close cooperation with the gynecologist familiar to the pregnant women. The gynecologist, who usually treats the women, is primarily recommended to carry out the conventional prenatal care for HIV1-positive pregnant women, according to current antenatal care guidelines, to preserve the bond with the patient’s familiar environment. Any other additional care measures should also be fitted in this setting. With the help of a well-planned time scheduling a closely-knit monitoring can be ensured.

Psychosocial care should be provided to each HIV1-positive expectant mother, at the latest in the HIV-specialized centers, and the opportunity to contact women’s AIDS self-help groups should also be offered. In the HIV-specialized centers the patients should be fully counseled regarding maternofetal transmission risks, current therapeutic options, the possibility to reduce mother-to-child HIV1-transmission rates, existing residual risks, potential short- and long-term effects of intrauterine exposure to anti-retroviral therapy for the child as well as the necessity of postnatal prophylaxis in the child and of avoiding breast-feeding, [30, 31, 32]. Considering the rapidly developing state of knowledge regarding HIV, up to date information is only warranted in such specialized centers. To overcome language barriers the help of interpreters should be obtained wherever necessary to ensure that all information reach the patients.

In co-operation between the general practitioner, the gynecologist, the obstetrician, the pediatrician and the patient, an individual, risk-adapted anti-retroviral treatment or prophylaxis concept corresponding to current German-Austrian guidelines for therapy in pregnancy should be set up. The general practitioner/infectious disease specialist should be consulted to adapt this therapeutic plan to ongoing therapies or prophylaxes against opportunistic infections. A switching of the treatment regime during pregnancy or the initiation of new therapeutic measures should only be undertaken upon consultation with a physician or center specialized in anti-retroviral therapy.

In the case of therapy-refractory morning sickness/ema gravidarum all anti-retroviral medications could be stopped simultaneously (An interruption of a combination of 2NRTI + NNRTI is problematic: Because of their short half-value period the 2NRTI disappear very fast after simultaneous interruption. In contrast to them the NNRTI has a longer half life with a high interindividual variability. NNRTI can be detected up to 3-4 weeks after interruption in some patients [141], which after disappearance of NNRTI’s implies a monotherapy with a high risk of development of resistance. See also 2.5) and reintroduced simultaneously, if the symptoms start to improve again in order to prevent the development of resistance anti-retroviral drugs (AIII).

Concurrently with the therapy, a monthly monitoring of blood counts is also recommended (AIII). Changes in blood counts are particularly significant because of the possibility of zidovudine-induced anemia and thrombocytopenia. If the hemoglobin-values drop to less than 10mg/dl in the expectant mother, it must be decided in close cooperation with the general practitioner whether waiting with closely-knit controls is possible or if the anti-retroviral regimen must be changed.

An oral glucose tolerance test is recommended between the 23rd (+0) and 27th (+7) weeks of gestation (GW) to screen for pregnancy-related diabetes, particularly if the expectant mother is treated with protease inhibitors (under protease inhibitor therapy diabetes mellitus occurs approximately three times more frequently) [33] (AIII). Measurements of blood lactate, liver enzymes, lipase and LDH should be carried out at the beginning of the pregnancy, after starting a therapy or prophylaxis, with suspicious clinical symptoms (signs of lactate acidosis such as nausea, severe vomiting, abdominal pain, fatigue, raised liver values) and particularly in the 3rd trimester because of the increased risk of lactate acidosis at the end of pregnancy (AIII).

Immunological and virological parameters (lymphocyte subsets, HIV1 viral load) should be checked at least bimonthly (AIII). The last measurement of HIV1-viral load before birth should be performed in time (2-4 weeks before birth), that the result is known at the latest at birth. In the case of an increased HIV1-viral load of the mother it is possible to intensify the anti-retroviral prophylaxis of the HIV1-exposed newborn to reduce the increased risk of vertical HIV1-transmission (see also 4.2) [72].

The expectant mother should be informed about any possible side effects and symptoms of the anti-retroviral therapy and should also be requested to inform their general practitioner immediately of any suspicious complaints [34, 35, 36]. Furthermore, she should also be requested to consult her general practitioner before taking any other prescribed or OTC medications during the pregnancy because of potential interactions with the anti-retroviral therapy (e.g. benzodiazepines).

Especially HIV1-positive pregnant women on methadone substitution or with drug abuse should be informed in detail about drug interactions between these drugs and anti-retroviral therapy/prophylaxis. Without continuous medical evaluation anti-retroviral therapy can lead to withdrawal syndrome, which jeopardizes success of anti-retroviral therapy due to lack of adherence.

A comprehensive diagnostic evaluation and therapy for genital infections is also important. Local co-infections such as chlamydiais, trichomoniasis and bacterial vaginosis amongst others correlate with higher HIV1-transmission risks, especially due to potential induction of premature labor [24]. The following examinations are obligatory: determination of vaginal secretion pH; sampling of a native preparation and micro-

</table>
biological culturing; STD diagnostics; toxoplasmosis screening at the start of therapy and in the second and third trimester to exclude a reactivation and/or new infection at the end of the pregnancy; a complete hepatitis serology. Urinary tract infections should be excluded e.g. by Urgitc examinations.

Up to 30% of HIV1-infected women display vulvar, vaginal and cervical dysplasias, which can progress more rapidly to carcinoma as a result of the HIV1-induced immune suppression [37]. For this reason a colposcopic examination should be carried out at the onset of pregnancy in addition to pap smear testing of the cervix and HPV-testing for high-risk-HPV-subtypes. If the colposcopic examination and HPV-testing yield normal results, the next control examination can be scheduled in a postnatal appointment. Any abnormalities must be controlled colposcopically and if necessary histologically (AIII). The perianal region should be examined in addition to the vulva, vagina and cervix, as also recommended for non-pregnant HIV1-infected women.

For all HIV1-infected expectant mothers nuchal translucency/transparency of fetus should be measured between the 10th (+6) and 13th (+6) weeks of gestation to estimate risks of aneuploidy. Fetal sonography (at least DEGUM stage 2) should be carried out between the 19th (+6) and 22nd (+6) weeks of gestation to screen for fetal malformations.

Invasive prenatal diagnostics should be avoided whenever possible. If there is an urgent indication, it should be performed with consideration of viral load and only under the protection of anti-retroviral therapy/prophylaxis because of the risk of contamination of the amniotic fluid [110,111] (AIII).

If the HIV-status of the mother is unknown and invasive prenatal diagnostic is indicated, an HIV-test should be offered again.

6-8 weeks after birth a detailed counseling about contraceptive methods is obligatory.

2. INDICATION FOR ANTI-RETROVIRAL TREATMENT AND THERAPEUTIC REGIMENS DURING PREGNANCY

2.1 INDICATION FOR ANTI-RETROVIRAL TREATMENT

Treatment indications [30] for adult HIV1-patients also apply to pregnant women (but check 3.1h!), i.e. in clinically asymptomatic women the immunological threshold for treatment is reached at a CD4-cell count below 350 CD4+ cells/mm³. It should be noted here that a certain degree of immunosuppression is induced physiologically by a pregnancy [20, 47] so that the CD4-values drop by around 10-20% during every pregnancy. In an HIV1-infected woman, this effect is may be even more pronounced (up to 40%). (AIII)

2.2 RESISTANCE TESTING

In order to ensure the efficacy of anti-retroviral prophylaxis/ therapy during pregnancy, testing for pre-existing resistance is generally indicated for every treatment naive pregnant woman before the start of anti-retroviral therapy or - prophylaxis [38, 39] (AIII).

For women who become pregnant during anti-retroviral treatment, German-Austrian guidelines for HIV1-therapy in adults recommend resistance testing (AIII) whenever a virological treatment failure is diagnosed.

If at the end of anti-retroviral HIV1-transmission prophylaxis (determined just before - or directly at the time of birth) viral load is detectable in pregnant women, resistance testing should also be performed in order to document the eventual development of resistance under prophylaxis, so that this can be taken into account if the woman requires anti-retroviral therapy at a later timepoint [41] (AIII).

If nevirapine ultra-short prophylaxis (single maternal dose immediately before birth) is given, resistance testing should be carried out 4-6 weeks after the anti-retroviral medication was stopped (see points 4 and 5) in order to determine, whether resistance against nevirapine has been induced [43,44] (AIII).

2.3. INITIAL THERAPEUTIC REGIMEN

(see Table 2)

Apart from the inhibition of viral replication in the mother, a major objective of an optimized initial therapeutic regimen during pregnancy is to combine an effective prophylaxis against HIV1-transmission with the highest possible degree of compatibility for mother and fetus. Restriction of subsequent maternal therapeutic options e.g. because of development of drug resistance should also be avoided.

A standard therapeutic regimen is usually a triple combination including two NRTI + either one (if necessary boosted) protease-inhibitor or + Nevirapin is recommended as an initial maternal therapeutic regimen[29] (AII). Efavirenz was excluded due to the reports of cerebral malformations in the newborns of efavirenz-treated pregnant monkeys [45]. Because 3 children with myelomeningoceles and one child with Dandy-Walker-malformation were born to women after treatment with Efavirenz in pregnancy[138], meanwhile Efavirenz was reclassified as FDA pregnancy category D. In addition, nucleoside analogues of particularly high mitochondrial toxicity (i.e. didoxycyctidine (dDC), stavudine (D4T) and didanosine(DDI)) should not be given in combination with one another wherever possible, because of the raised risk of a potentially fatal lactate acidosis in the expectant mother [46] (AIII).

It has to be considered that with the exception of zidovudine, no anti-retroviral drug has been approved for therapy during pregnancy and that the limited experience until now has not permitted any definitive evaluation of the risks and benefits. When choosing anti-retroviral drugs one must also keep in mind that the pharmacokinetics of each drug group (NRTI, NNRTI+PI) can be altered during pregnancy [48, 49, 50]. Therefore during use of PI and NNRTI in pregnancy drug monitoring is compulsory.

2.4. MANAGEMENT OF HIV1-POSITIVE PREGNANT WOMEN WITH HEPATITIS CO-INFECTION

It is urgently necessary to treat hepatitis-/-HIV-co-infected pregnant women in an interdisciplinary setting including an infectious disease specialist.
Table 2. Comments on the initial anti-retroviral combinations/substances.

<table>
<thead>
<tr>
<th>Initial combinations and substances</th>
<th>Comment</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Nucleoside analogs</strong> &lt;br&gt; for which most experience has been gained</td>
<td>Zidovudine + Lamivudine (also as Combivir®) &lt;br&gt; Most clinical experience has been gained with the use of these substances. One additional rationale for application of zidovudine is the metabolization of this drug in the placenta which might contribute to the transmission preventing effect [51, 52]. Some cases of lethal mitochondrialopathies were reported in non infected children after maternal zidovudine/lamivudine-therapy [7, 8]. Data about long term toxicity especially carcinogenicity/genotoxicity as a matter of incorporation of nucleoside analogs into DNA [112] are lacking. In case of therapeutic failure changed pharmacokinetics of nucleoside analogs because of pregnancy must to be taken into consideration [113].</td>
</tr>
<tr>
<td>Alternatives</td>
<td>stavudine + Lamivudine &lt;br&gt; Didanosine + Lamivudine &lt;br&gt; Abacavir &lt;br&gt; Tenofovir:</td>
</tr>
<tr>
<td></td>
<td>Less clinical experience in pregnancy. Increased attention relating to potential side effects. Use of Abacavir only after testing for HLA-B*5701[136] to avoid hypersensitivityreaction. So far no increased rate of malformation in humans [57], but individual reports of malformations [67]. In animal studies, where Tenofovir was applied in higher doses than usual in humans, reduced bone density and renal damage were observed [135].</td>
</tr>
<tr>
<td><strong>NNRTI</strong></td>
<td>Nevirapine:</td>
</tr>
<tr>
<td></td>
<td>Caution: raised liver enzymes, more allergic reactions since pharmacokinetics are altered during pregnancy [49]. Increased liver toxicity in pregnancy especially with CD4-counts &gt;250/µl. With longer administration enzyme induction of the cytochrome P450 system and therefore accelerated metabolization of nevirapine not only in the expectant mother but also in the newborn is therefore not sufficient for prophylaxis of HIV-1-transmission, if nevirapine has already been given over a longer period during the course of the pregnancy.</td>
</tr>
<tr>
<td><strong>Protease inhibitors, for which most experience has been accrued [50]:</strong></td>
<td>In common:</td>
</tr>
<tr>
<td></td>
<td>Lopinavir + Ritonavir (=Kaletra®) or Saquinavir (Fortovase®) + Ritonavir</td>
</tr>
<tr>
<td></td>
<td>Because of the poor ability of most PIs to cross the placenta (no or poor data: Fos-Amprenavir [57, 113, 125], Darunavir [57, 113], Tipranavir,) no therapeutic levels are to be expected in the fetal compartment [54, 55, 56]. As such, no relevant adverse effect frequency is to be expected amongst the fetuses, but it is still unclear whether therapeutic drug-levels in the fetus are necessary or helpful to inhibit vertical HIV-1-transmission. No increased rate of malformations in humans [57, 126]Until now rare published studies about the use in pregnancy [54, 57, 113] but as yet no incidence for unusual or unexpected adverse effects [57].</td>
</tr>
<tr>
<td>Alternatives:</td>
<td>Nelfinavir</td>
</tr>
<tr>
<td></td>
<td>Ritonavir</td>
</tr>
<tr>
<td></td>
<td>Indinavir + Ritonavir</td>
</tr>
<tr>
<td></td>
<td>Up to now most experiences in pregnancy have been accrued for Nelfinavir [57, 113, 126], but an anti-retroviral therapy with an unboosted PI is no more recommended as optimal therapeutic regimen in adults [29].</td>
</tr>
<tr>
<td></td>
<td>Contraindicated as a mono-PI because of poor compatibility; can be applied at low doses to boost plasma levels of other PIs.</td>
</tr>
<tr>
<td></td>
<td>High number of tablets, relevant side effects [57]. With Indinavir there is an increased need for water uptake to prevent the formation of kidney stones in the mother.</td>
</tr>
<tr>
<td><strong>New substances:</strong></td>
<td>T-20 (fusion inhibitor)</td>
</tr>
<tr>
<td></td>
<td>Atazanavir</td>
</tr>
<tr>
<td></td>
<td>Emtricitabin</td>
</tr>
<tr>
<td></td>
<td>Fosamprenavir</td>
</tr>
<tr>
<td></td>
<td>Tipranavir</td>
</tr>
<tr>
<td></td>
<td>Darunavir</td>
</tr>
<tr>
<td></td>
<td>Maraviroc</td>
</tr>
<tr>
<td></td>
<td>Raltegravir</td>
</tr>
<tr>
<td></td>
<td>Should only be used in heavily pretreated pregnant women as part a of anti-retroviral salvage therapy based on resistance testing. Because of the high molecular weight a transplacental passage is not expected and could so far not proved [121]. Some case reports show no adverse effects [57, 127].</td>
</tr>
<tr>
<td></td>
<td>Insufficient data for use in pregnancy [28, 57, 113], does not cross placenta [127].</td>
</tr>
<tr>
<td></td>
<td>As yet at the most single case reports [80], no recommendation due to the risk of malformations possible [57].</td>
</tr>

ZDV, zidovudine; ART, anti-retroviral combination therapy with usually three medications: two nucleosid reverse transcriptase inhibitors + a protease inhibitor (PI) or nevirapine; 3TC, lamivudine; ddd, didanosine; d4T, stavudine; NVP, nevirapine; EFV, efavirenz; VL, virus load
2.4.1 Management of HIV1-positive pregnant women with Hepatitis B virus (HBV) co-infection

According to the German-Austrian guidelines for the therapy of HIV1-infection in adults [30] an anti-retroviral three drug regimen including Tenofovir plus 3TC or Tenofovir plus FTC, which all three have for antiviral activity for hepatitis B, is also recommended for HIV-positive pregnant women with Hepatitis B co-infection. Because of alarming study results in pregnant animals [135, see also 2.3] Tenofovir should be used with caution in pregnancy. In the special case of HBV co-infection in HIV-positive pregnant women the risk-benefit analysis will more often result in the use of Tenofovir, because of the advantage in therapy of Hepatitis B.

Interferon-alpha and pegylated interferon-alpha are not recommended during pregnancy.

After starting anti-retroviral therapy in pregnancy a HIV/HBV co-infected pregnant women should be monitored at close intervals. Not later than two weeks after start of therapy the first laboratory control has to be performed. Thereafter monthly controls are adequate.

If the anti-retroviral therapy will be ceased after pregnancy (no maternal - but fetal indication for therapy) severe flare-up’s of HBV disease should be taken into account and the close laboratory controls must be continued after birth. In case of an indication for therapy of hepatitis B-infection only, after birth a change in therapy to drugs against HBV with no anti-HIV activity is possible.

All infants born to HBV-infected women should receive hepatitis B immune globulin (HBIG) and initiate the three dose hepatitis B vaccination series within 12 hours.

2.4.2 Management of HIV1-positive pregnant women with Hepatitis C virus (HCV) co-infection

Because maternal HCV-infection increases the risk of vertical HIV-transmission, an effective anti-retroviral combination therapy is recommended for HCV/HIV co-infected pregnant women.

An effective anti-retroviral HIV-therapy during pregnancy also reduces mother-to-child transmission of HCV.

In HIV/HCV co-infected pregnant women laboratory examination should be performed two weeks following initiation of anti-retroviral therapy and then at least monthly.

Pegylated interferon-alpha is not recommended - and ribavirin is contraindicated during pregnancy because of teratogenicity (FDA category X).

Decisions concerning the mode of delivery in HIV/HCV co-infected pregnant women should be based on considerations related to HIV infection alone.

2.5. INTERRUPTION OF ANTI-RETROVIRAL THERAPY DURING THE 1ST TRIMESTER OF THE PREGNANCY

The decision to interrupt maternal anti-retroviral therapy in the 1st trimester of pregnancy depends on the individual clinical, immunological and virological status of the pregnant woman as well as the anti-retroviral treatment case history. If the patient was clinically symptomatic before the start of anti-retroviral therapy, or if immunological and/or virological parameters showed an advanced state of immune deficiency and/or a very high risk for rapid disease progression, interruption of therapy is fraught with greater risks for the pregnant women than it is for a clinically asymptomatic woman, whose laboratory parameters might justify the start of an anti-retroviral therapy, but whose clinical status is stable and whose laboratory parameters are no cause for major immediate concern.

It must necessarily mentioned, that up to now all randomized trials of structured treatment interruption/STI versus continuous therapy, especially the SMART-study [139] (interruption of therapy with CD4 >350/µl and restart of therapy with CD4 <250/µl versus continuous therapy), showed a more worse outcome in the STI-group according to cardiovascular disease, opportunistic infections, AIDS, death etc.

Vertical HIV1-Transmission occurs very rarely during the first 12 weeks, and is most common at the end of pregnancy and during birth. Therefore an effective HIV1-transmission prophylaxis does not require anti-retroviral therapy during the entire pregnancy. Since currently adverse side effects (especially during the organogenesis) can not be excluded, particularly with application during the first trimester, an at most 3 month interruption of maternal anti-retroviral therapy should be taken into consideration [133,134]. The decision to interrupt anti-retroviral therapy in the first trimester of pregnancy should be made individually and according to individual risk profiles with the informed consent of the mother. If therapy is interrupted, monitoring intervals should be short (at least monthly measurement of t-helper cell number and the virus load) (AII,III).

Up to now, no results of controlled trials have been published regarding the risks associated with interruption of anti-retroviral therapy during pregnancy, and inadequate data exist to allow any estimation of the risk that anti-retroviral combination therapy during the 1st pregnancy trimester entails for the child [12,57].

From an embryo-toxicological standpoint, no drugs with unclear human teratogenic potential should be applied in the first trimester until the 11th completed week of gestation + 0, (after the last regular menstruation) due to their potential effects on organogenesis [58,59,60].

If a decision is made in favor of therapy interruption, all anti-retroviral medications should be ceased. In regimes consisting of 3NRTI or 2NRTI + PI the simultaneous interruption of all drugs can be managed without problems.

In contrast, because of a possible long half-life up to 3-4 weeks of NNRTI [141] with a high interindividual variability, simultaneous interruption of an anti-retroviral combination therapy with 2NRTI + 1NNRTI (such as efavirenz and nevirapine) results in a temporary monotherapy with a high risk of development of NNRTI-resistance. At present the most safe management of this problem in non-pregnant individuals is to replace the NNRTI by a (boosted) PI and cease this

* Beware: Presently only a few clinical results have been published regarding the application and dosing of lamivudine with (extreme) premature infants.

* Beware: if the HIV1-positive expectant mother has been treated for a longer period of time with nevirapine during pregnancy, an enzyme induction may occur that may lead to a more rapid breakdown of nevirapine in the newborn.
new anti-retroviral treatment after 4 weeks. As an alternative the 2NRTI are continued over 4 weeks after stopping NNRTI (if possible under monitoring the NNRTI-level via therapeutic drug monitoring) [29, 122]. Because a pregnancy is usually observed not before some weeks after conception, an additional 4 weeks lasting procedure to interrupt a regimen with 2NRTI+NNRTI interferes with the avoidance of these drugs during organogenesis. Therefore a prompt interruption of NNRTI-containing regimens can hardly be arranged in the first 6-8 weeks of gestation (where most organs develop) and therefore can not be recommended. Nevertheless an interruption of a combination with NNRTI in the remaining weeks should be guided by an HIV-experienced infectious disease specialist to minimize the development of drug resistance.

The anti-retroviral treatment should not be resumed before the 13th (+0) week of pregnancy in order to take into account the uncertainties in the exact time of conception.

If a woman under anti-retroviral therapy has planned for a child, a pregnancy test (HCG) should be undertaken very early on. The pregnancy test becomes positive 6-8 days after conception, thus a decision to interrupt anti-retroviral therapy can be made accurately in time. On the other hand because the time until conception cannot be calculated and can last very long an anti-retroviral therapy should never be stopped before conception even when the pregnancy is planned.

If a HIV1-positive women plans to get pregnant, if possible no Efavirenz containing ART should be started or Efavirenz containing regimes should be changed to regimes with other components (for example boosted PI, Nevirapine) in time.

After interruption in the first trimester therapy with the same drugs can be restarted (exceptions: efavirenz, combination of stavudine + didanosine, provided that therapeutic alternatives are available) [45, 46], since resistance development is not to be expected [32, 33] (AI,III).

These recommendations also apply if pregnancy is first diagnosed during the course of the 1st trimester.

3. HIV1-TRANSMISSION PROPHYLAXIS WITH STANDARD RISK PROFILE (SEE TABLE 3.1)

Prophylactic scheme (= no maternal treatment indication, criteria see table 3.1!!!):

3.1a) Viral load in the expectant mother < 10,000 genome copies/ml: In this situation two alternative regimens can be used:

I. Zidovudine application from the completed 30th (or 28th) (+0) GW at an oral dose of 2x250 mg.

II. Temporary anti-retroviral combination therapy with 3 drugs (HAART, but if possible no Efavirenz) from week of gestation 30+0 (28+0) until immediately after birth

Comments to opportunity I:

Provided that there is no primary resistance to zidovudine, a reduction of viral load at birth can be achieved under a zidovudine-monoprophylaxis from a low initial virus load. This suffices - particularly in combination with a planned cesarean birth - for minimizing the risk of transmission to the child [5, 71, 72, 124, 131, 132]. The advantage in comparison with HAART is the lower risk of prophylaxis-associated toxicity for mother and child. Because of the short duration of this monoprophylaxis and of the comparatively high resistance barrier of zidovudine the risk of developing a resistance against zidovudine should be very low [68, 115]. In comparison to HAART the risk in monoprophylaxis (provided a good adherence to both regimens) is higher that viral load is not reduced sufficiently until birth.

Comments to opportunity II:

Under a temporary standard anti-retroviral therapy (HAART) from week of gestation 30+0 (28+0) until immediately after birth the low viral load can be decreased under limit of detection at birth with a high probability [5, 71, 130, 131, 132]. Because of the long half life (which can induce resistance during a cessation after birth) and increased toxicity in patients with CD4-cells higher than 250/μl, this prophylactic HAART should not contain Nevirapine. Ideal for prophylaxis are regimens with a (boosted) PI [29]. Provided a good adherence the risk of induction of a drug resistance is lower than in a monoprophylaxis with zidovudine. Disadvantage of a prophylaxis with HAART is the higher drug burden for mother and child, which can lead to more adverse effects and toxicities than in a monoprophylaxis. These complications can reduce adherence and then result in development of drug resistance [114]. On the other hand changed pharmacokinetics of anti-retrovirals in pregnancy (published for Indinavir; for many other anti-retroviral drugs no pharmacokinetic data in pregnancy exist) can induce drug resistance [41, 61, 62, 63, 64, 65, 66, 68, 69, 70, 113].

In the decision to use a monoprophylaxis with zidovudine or HAART in pregnant women with a viral load < 10,000 genome copies/ml also the elevated rate of prematurity under HAART, which increases vertical transmission of HIV, must be taken into account [101, 115, 116].

3.1b) Viral load in the expectant mother >10,000 HIV-genome copies /ml: The risk of vertical transmission is directly proportional to the viral load in the pregnant women. If there is not yet a distinct maternal indication for treatment (CD4 cell count >350/μl), but the viral load is higher than 10,000 virus copies/ml, a temporary anti-retroviral standard combination prophylaxis (without efavirenz !) is recommended from GW 30 +0 (or 28 + 0) to immediately after delivery, since a zidovudine monoprophylaxis is not able to reduce the viral load with adequate certainty (raised risk of transmission with VL > 10,000 [5, 62, 71, 72, 73, 74] (AI,II).

In case of a very high viral load (>100 000HIV-copies/ml) a start of anti-retroviral prophylaxis can considered in GW 28+0. The early start of prophylaxis allows for controls of success of anti-retrovirals at an early stage (e.g. in GW 32+0). If a change of anti-
retroviral prophylaxis is necessary at that timepoint, for the new regimen there is enough time until birth to suppress viral load as much as possible.

3.2 Primary cesarean section is available between 37 (+0) to 37 (+6) gestational week utilizing an operation technique which avoids excessive bleeding, performed rapidly by the most experienced obstetrician [75,76]. The benefit of the elective cesarean section for transmission prophylaxis in patients under an anti-retroviral combination therapy or prophylaxis with a low viral load in the plasma, is not evidenced and is still a matter of dispute (see point 6 for a detailed discussion of the mode of birth) (A/II).

3.3 Pre- and intra-operative intravenous zidovudine application starting 3 hours before cesarean section (2 mg/kg as a loading-dose for 1 hour followed by 1 mg/kg until the delivery of the child according to the original ACTG 076 protocol), even if zidovudine is not a component of the maternal therapy/ prophylaxis during the pregnancy [77] (AI).

3.4 Postnatal zidovudine application for the child over 2-4 weeks orally (2 mg/kg every 6 hours) or 10 days i.v. (1.5 mg/kg every 6 hours) [78] (AI).

Since a higher prevalence of zidovudine-resistant HIV1-strains can be expected in the future [40], the presence of wild-type HIV1 should be confirmed genotypically in the expectant mothers before zidovudine is applied (exclusion of genotypic resistance).

4. RISK-ADAPTED TRANSMISSION PROPHYLAXIS (SEE TABLE 3.2)

For birth-related HIV1-transmission risks, HIV1-transmission prophylaxis should be escalated in a risk-adapted manner.

4.1 Multiple pregnancy, premature labor and premature infants 33rd(+0) - 36th(+6)GW and maternal viral load 3 000-10 000 HIV-copies/ml before birth

Because of the increased risk of premature birth in multiple pregnancies, prophylactic zidovudine application should already be started from the 29th (+0) week of gestation (AIII).

In case of premature labor, anti-retroviral combination prophylaxis should be started immediately (with e.g. zidovudine + lamivudine + PI), if the pregnant women is not yet receiving a combination therapy, if a cesarean birth is not indicated because of immaturity of the baby and if labor can still be stopped (AIII).

If a premature birth is unavoidable, the procedure described in 4.2 should be followed.

If e.g. because of a premature delivery etc. the viral load of the mother is between 3 000 – 10 000 HIV-copies/ml before birth, the postnatal prophylaxis should be prolonged according to the ACTG 076-study protocol, where zidovudine is applied over 6 weeks orally [14,63]. The newborn should be closely monitored during this prolonged prophylaxis. If problems such as anemia, neutropenia or lactate acidosis occur, benefits and risks of continuing the prophylaxis should be carefully weighed, and in doubt prophylaxis should be discontinued (A/III).

4.2 Amnion infection syndrome/amnionitis, premature rupture of membranes > 4h, premature birth <33rd(+0) GW and viral load increase at the end of pregnancy >10 000 HIV-copies/ml

In these obstetric emergency situations the transmission risk is greatly increased [3, 5, 15, 16, 72, 79, 132]. The prepartal part of the prophylaxis should (as long as a standard combination therapy/prophylaxis is not already being given) be intensified by an (additional) dose of nevirapine as long as this is still possible [83].

Postnatally, transmission prophylaxis can also be escalated in the newborn through application of nevirapine in addition to a combination prophylaxis with zidovudine + lamivudine [82, 83, 84]. In this case one dose of nevirapine should be given to the newborn after 72h if the mother has already received one dose prepartally (minimum 2 hours before birth). Two doses should be given if the mother did not receive a prepartal dose or if less than two hours have elapsed between nevirapine application to the mother and birth [56, 81, 83]. If two doses are given, the first should be given immediately and the second within 72h after birth (AI,III).

Under nevirapine ultrashort monoprophylaxis (one dose of nevirapine shortly before birth) there is a considerable risk of resistance development in the mother (>20%). To reduce this risk either continuous combination therapy (in the case of treatment indications for the mother) or transient combination therapy - e.g. additional 2 NRTI's over a period of 1 week after oral nevirapine should be considered as a possible protective measure against resistance development (see also the strategies described under 2.5/ therapy interruption). So far no evidence base for this strategy.

2-4 weeks after termination of transient combination therapy or ultrashort monoprophylaxis it should be evaluated, whether resistance has been induced by resistance testing.

If the HIV1-positive expectant mother was treated with nevirapine for a longer period during the pregnancy, an enzyme induction might result in the newborn so that a more rapid breakdown of nevirapine occurs [53]. For this reason, with longer nevirapine therapy of expectant mothers during pregnancy, the drug must be applied at higher doses to the newborns (4 mg/kg).

The preferred mode of delivery is immediate cesarean section if the rupture of membranes does not already date back longer than 4 hours. For intervals >4 h after (premature) rupture of membranes, no advantage of cesarean section regarding transmission risks can be expected [85]. However, the decision to implement this must be based on obstetric considerations.

Rupture of membranes between the 24th and 28th gestational weeks represents a particularly problematic special case. Steroid induced pulmonary maturation in the unborn is not effective before 24 hours after application and therefore contradicts measures required for preventing HIV1-transmission. In this case the high risk of permanent damage to the child due to lacking
pulmonary maturation and the increased HIV1-transmission rate must be carefully weighed up.

4.3 INCISION INJURY TO THE CHILD/ ASPIRATION AND/OR INGESTION OF BLOODY AMNIOTIC FLUID

With an incision injury to the child during caesarian section, or if bloody amniotic fluid can be aspirated from the stomach and/or the lungs, a percutaneous inoculation or a mucosal exposure to virus-containing body fluids must be assumed [23]. This justifies an intensification of the usual standard pediatric prophylaxis to a combination prophylaxis consisting of two NRTI-s consistent with post-exposure prophylaxis recommendations for adults [86] (AIII). An extended application of nevirapine (exceeding the ultra-short prophylaxis) for post-exposure prophylaxis can not be recommended at this time because of the lack of data regarding pharmacokinetics and safety.

Because of the lack of experience and formal approval of protease-inhibitors and NNRTIs for the therapy of newborns, and because of the dearth of comparative studies on the efficacy of double NRTI and triple drug post-exposure prophylaxis regimens, the recommendations for treatment escalation are limited to measures that have been proven effective and tolerable within the context of mother-to-child transmission prophylaxis. For these reasons the postexpositional prophylaxis of newborn with high risk of HIV-transmission should be limited to two NRTI-s combined with one or two doses Nevirapine.

5. PROCEDURES WITH INCOMPLETE TRANSMISSION PROPHYLAXIS

5.1 WITH VERIFIED HIV1-INFECTION

If despite of a known HIV1-infection no transmission prophylaxis has been carried out until the time of birth, this should be done at the latest during delivery and postnatally. A benefit for the newborn can even be expected with incomplete transmission prophylaxis [63,64,87,88,89]. A combination of a nevirapine ultra-short prophylaxis (one dose preparately for the mother, one dose postnatally for the newborn or 2 doses postnatally) with a six-week zidovudine or zidovudine + lamivudine application for the newborn is then recommended (AI).

According to data from the HIVNET 012 study, a single dose of nevirapine shortly before birth combined with a single dose given to the newborn within 72 hours of birth is more effective in preventing vertical transmission than the immediate pre- and intrapartal administration of zidovudine combined with a week long postnatal administration of zidovudine to the newborn [87]. (Measures of maternal short time nevirapin prophlaxis see also 4.2)

Zidovudine prophylaxis started within 48 hours after birth according to the ACTG 076 protocol (application over 6 weeks) can still lower the HIV1-transmission rate. In a retrospective US study a transmission rate of 9.3 % has been reported with initiation of zidovudine therapy in the first 48 hours after vaginal delivery, as compared to a rate of 18.4% for a later on-set of therapy (>48 h). Without any therapy, 26.6 % of the children became infected[64].

5.2. SITUATION WITH AN UNCLEAR HIV1-INFECTION STATUS

If a patient presents late in her third trimester without HIV-Test and sufficient time remains to perform a screening test (and if necessary a confirmatory test), this should be offered without delay, so that intrapartal and postpartal transmission prophylaxis can be carried out whenever the test proves positive [64].

The HIV-antibody test should be accompanied by competent personal counseling, provided if necessary by an appropriate institution [1,2]. The refusal to undergo HIV-antibody testing must be respected.

In cases when the HIV status of the pregnant women is unknown and there is no time to carry out regular testing and counseling, an HIV-rapid test should be offered and prophylactic measures can be instituted with positive rapid test results. During counseling the pregnant women about HIV-rapid tests, it should considered, that in spite of accurateness of these tests (sensitivity and specificity of HIV-rapid tests achieve results of >99,5%) the probability, that a positive HIV-rapid test is positive in confirmatory tests can be less than 50% in the view of the low prevalence of unknown HIV1-infections in pregnant women (estimated about 50-100 cases per 200.000-300.000 untested pregnant women until 2007). Therefore every positive HIV-rapid test must be confirmed by HIV-Elisa or HIV-Westernblot. If the confirmation fails, all measures to avoid HIV1-transmission must be ceased immediately.

An opportunity to further increase the specificity arises from controlling a positive rapid test finding with a second rapid test procedure. If the second test reports a negative finding, the probability is high that the first test result was false positive.

6. MODE OF DELIVERY

Studies, analyzing HIV1-positive pregnant women and their children before the beginning of the HAART-era, showed a significant reduction of mother-to-child-transmission of HIV1 by a primary cesarean section. Delivery by elective cesarean section (before the onset of labor) resulted in a reduction of the vertical transmission risk by approximately 50%, i.e. in a 8.2% vs. 16.8% risk associated with vaginal birth[76]. Elective Cesarean section should therefore represent an essential component of every prophylactic HIV1-transmission regimen (AI,II). On the other hand some studies which compared healthy pregnant women with HIV1-infected pregnant women showed a higher rate of complications as cause of cesarean section (e.g. higher rates of fever, hematoma and wound infection [117, 118, 139]) in HIV1-positive women. In contrast other studies failed to prove these disadvantages of cesarean section [97, 98, 99, 100].

According to recent examinations the protective effect of cesarean section in HIV1-positive women, who were treated with HAART in pregnancy and whose HIV-viral load was under limit of detection at the end
of pregnancy, seems to be minimal [132, 137, 138]). Hence a vaginal delivery is arguable under these optimal conditions (HAART in pregnancy, HIV-viral load in pregnancy especially shortly before birth under limit of detection), when it is the request of the pregnant women and no obstetric risks argue against it.

Practical procedure in the delivery room:
Preoperative/ intra-operative i.v. zidovudine therapy of the mother at a dose of 1 mg/kg/h after a loading-dose of 2 mg/kg over 1 hour until delivery still represents a prophylactic measure independently of mode of delivery (AI, AII).

a) The elective, primary cesarian section should be carried out by the most experienced obstetrician available utilizing an operation technique which avoids excessive bleeding, performed between 37 (+0) to 37 (+6) gestational week on a labor-free uterus under i.v. application of zidovudine. Because of lower maternal complications (pneumonia/fever) and the possible early bonding in delivery room a local anesthetic procedure (e.g. spinal anesthesia) is preferably recommended [97].

b) To keep the risk of vertical HIV transmission as low as possible during an intended vaginal delivery some special features have to be considered:

Invasive monitoring of the newborn (sampling of microbloodprobes from fetal scalp, scalp electrodes etc.) should not be used. A maybe necessary amniotomy has been performed as late as possible. An operative vaginal delivery should be avoided. Especially in case of protracted labour, abnormal fetal heart rate or suspicion of AIS/amnionitis etc. the indication/decision for a (secondary) cesarean section should be taken into account generously and earlier as usual.

It should be noted that an increased rate of premature birth has been documented on several studies in mothers treated with an anti-retroviral combination therapy [101]. However, two large American studies [5, 36] failed to find an increased rate of premature birth under HAART. Considering these contradictory findings, in the last trimester special attention must be paid towards women with anti-retroviral combination therapy or other risk factors for premature birth so that a premature birth or other emergency mode of birth under unfavorable conditions can be avoided. This is warranted by frequent antepartum controls in the third trimester and, under certain conditions, early hospitalization.

It is urgently recommended that an HIV post-exposure prophylactic emergency set be kept in stock by the hospital and that all medical personnel involved is informed about an emergency plan including indications and procedures related to HIV post-exposure prophylaxis (PEP) after occupational HIV exposure (e.g. following needle prick or knife injuries to the operating surgeon). For actual German-Austrian PEP guidelines see www.daignet.de under HIV-therapy.

7. Care of the newborn in the delivery room

Amniotic fluid can be contaminated with HIV1 by the opening of the amniotic sac during both a spontaneous delivery and a cesarean section. With a vaginal delivery there is also the possibility that virus-contain-

8. Postnatal transmission prophylaxis in case of standard risk

The recommendation of oral zidovudine application over 6 weeks to the child at a dose of 2 mg/kg every 6 hours results from the findings of the ACTG 076 study [14]. After oral zidovudine application during pregnancy, intravenous zidovudine infusion during birth, and elective cesarean section, this represents the fourth component of HIV1-transmission prophylaxis. A desacelation of the six-week postnatal component (according to the ACTG-076 protocol) of the transmission prophylaxis is justified by the results of a study carried out in Thailand involving a shortened zidovudine regimen and considering experience gained in Germany until now. The Thai study showed that the six week therapy produced an additional benefit as compared to a three day postnatal zidovudine dosage when the duration of prepartal prophylaxis was very short (from the 36th week of gestation with spontaneous delivery as the predominant mode of birth) [63]. In Berlin, satisfactory results (no transmissions) have been achieved (involving a small number of cases, n = 57 [78]) with an i.v. dosing of 1.3 mg/kg every 6 hours over 10 days if the prepartal prophylaxis was started in the 32nd week of gestation. The majority of experts conclude from this that postnatal zidovudine should be given to the child, although they consider a reduction of the duration of postnatal zidovudine transmission prophylaxis to 2 to 4 weeks (2 mg/kg orally every 6 hours) as usually sufficient (AI,III). Exceptions to this rule include pregnancy and birth complications as well as failure to implement a maternal prophylaxis (see 4.2, 4.3 and 5.1).

9. Refraining from breast feeding

Breast-fed children of HIV1-positive mothers are infected twice as frequently as formula-fed children of HIV1-infected mothers. The HIV viruses and HIV1-infected lymphocytes detectable in breastmilk as well as inflammation/injuries of the nipple or the mammary
10. POSTNATAL CARE OF THE HIV-EXPOSED CHILD AND PREPARATION OF A SURVEILLANCE REGISTER

From the 32nd week of gestation IgG antibodies, including also IgG antibody against HIV-1, are transmitted from the mother to the fetus across the placenta. Since the conventional HIV-1 test is an antibody test, all, i.e. even non-infected children of HIV-1-infected mothers, are serologically HIV-1-positive until the maternal antibodies disappear.

Detection of HIV-1 during the first two years of life must therefore be completed using HIV-1-PCR based methods. It is possible to detect either HIV-1-DNA or HIV-1-RNA. Up to now it is unclear which test procedure is the more sensitive with respect to the special situation of neonatal infection diagnostics. All positive HIV-1 test results should be confirmed as rapidly as possible by a second blood test.

It should be noted that commercially available HIV-1-PCR kits do not cover all HIV-1-subtypes or mosaic viruses (not subtype B) and may provide false negative results [106]. With an HIV-1-positive parent that might be infected with a subtype other than B (especially if the patient originates from outside Western Europe / North America), maternal blood must always be analyzed as a positive sample in addition to the child’s blood (if possible before the onset of an anti-retroviral therapy / prophylaxis of the mother).

If the maternal blood is unambiguously HIV-1-positive in the PCR, the result of the HIV-1-PCR of the child should also be utilized. If the detection of HIV-1 nucleic acids fails with maternal blood (negative or borderline findings), the HIV-1-PCR analysis of the child’s blood can not be relied upon. Then, either a special examination must be initiated using subtype-adapted PCR primers in specialized laboratories, or the disappearance of the maternal HIV-1-antibody at the end of the 2nd year of life must be waited for in order to reliably exclude an HIV-1-infection in the child.

If the HIV-1-antibodies in the HIV-1-exposed child persist, an HIV-1-infection must be assumed. As a matter of definition, HIV-1-exposed children are regarded as HIV-1-negative if an HIV-1-Western blot proves completely negative with normal immunoglobulin concentrations.

Amongst children of HIV-1-positive mothers, two negative HIV-1-PCR findings are required to exclude an HIV-1-infection. The first HIV-1-PCR should be performed one month after birth (in the age of 28 days: sensitivity 96%, specificity 99%[129]); the second one after the third month of life, because at this time-point the sensitivity and specificity of the HIV-1-PCR is considered to be sufficiently high [107].

With the HIV-1-PCR test in the first month of life a high rate of HIV-1-infected children can be diagnosed. This is important for starting prophylaxis against Pneumocystis carinii as early as possible (if possible 4-6 weeks after birth where HIV-1-transmission has occurred) and the early-life anti-retroviral therapy in the first months of life.

With negative HIV-1-PCR findings as well, disappearance of maternal antibodies in HIV-1-exposed children should be documented at least once.

It must be stressed here that because of the intrauterine and postnatal exposure of a child to anti-retroviral substances with still unknown long-term consequences, clinical surveillance of the children is indispensable to get aware of any long-term damage.

11. HOTLINE, NOTIFICATION OF UNEXPECTED OBSERVATIONS AND EXPERIENCES

Honorary telephone hotline for problems regarding HIV infection during pregnancy and in HIV-1-exposed newborn:

- Gynecologic problems: 0178 - 282 0 282
- HIV-therapy in pregnancy: 0178 – 673 1661
- Pediatric problems: 0178 - 41 21 313

Further updating of the recommendations:

Since only little or even no results or information are available regarding the application of newer drugs or combinations of drugs during pregnancy or in newborns, all physicians involved in this work are urgently invited to inform us of any new or unexpected observations and results, e.g. by notifying us by e-mail at the address given in the "address for correspondence", or by notifying the "anti-retroviral Pregnancy Registry" (APR), the largest register for recording experiences with anti-retroviral substances during pregnancy:

- Tel-no.: +1-910-256-0238
- Fax: +1-910-256-0637 or +44 1895 825 005
- Website: www.APRegistry.com
